Abstract—We numerically study the synchronization of two semiconductor lasers, which have optical self-feedback loops and are subject to injection of common driving light with fast and randomly fluctuating phase and amplitude. We show that the synchronization is possible for broadband random light injection, and clarify the properties of this type of synchronization in detail.

1. Introduction

A variety of physical systems exhibit oscillatory dynamics. Such systems are as diverse as electrical circuits, chemical reaction systems, and neuronal networks. It is well known that these systems can exhibit various types of synchronization phenomena [1, 2]. Lasers are typical such oscillatory systems and exhibit various synchronization phenomena via electrical or optical signals [3, 4].

Recently, it has been revealed that a common random input could give rise to synchronization between two independent limit-cycle or chaotic systems [5, 6, 7, 8, 9, 10, 11, 12]. This type of synchronization has been experimentally observed in semiconductor lasers driven by common light, in which both the amplitude and phase fluctuate randomly [13, 14] or only the phase fluctuates randomly with constant amplitude [15].

The synchronization of lasers has potential applications to secure communications, and many studies have been made for this issue (e.g., [3, 4]). Recently, we have proposed a secure key distribution scheme using correlated randomness in lasers synchronized by injection of common random light with broad bandwidth, which has a fast randomly fluctuating phase or amplitude [16]. The security of this scheme relies on the difficulty of completely observing the broadband common random light with current technology. Such approach using the limits of observation technology is called bounded observability approach [17]. In order to achieve higher security in the above scheme, it is necessary to use a common random light with broader bandwidth, which is more difficult to completely observe. In the experiments in Refs. [13, 14, 15], the bandwidth of common random light was of the order of a few GHz, which is not broad enough. It is an important issue to clarify the nature of synchronization phenomenon in broader bandwidth regime beyond the regime of a few GHz.

Figure 1: Illustration of the laser system configuration.

In this paper, we consider two semiconductor lasers with optical feedback loops and subject to injection of common random light with much broader bandwidth up to the order of THz. We numerically investigate the condition for their synchronization in detail, focusing on its dependence on the parameters which characterize the lasers or the random light.

2. Model and simulation method

Figure 1 illustrates the configuration of laser system of our study. A portion of light from a random light source (RLS) is injected into two semiconductor lasers, which we call response lasers (RL1, 2). The light has randomly fluctuating phase and amplitude. In experiments, the RLS can be realized by using a super luminescent diode. This optical coupling is unidirectional from the RLS to the response lasers. Each response laser has an external mirror (M) to form an optical self-feedback loop. The loop includes a phase modulator (PM) to vary the phase \( \theta_{1,2} \) of the feedback light.

To model the system in Fig. 1, we use the Lang-Kobayashi equation with optical injection [18]:

\[
\frac{dE_j}{dt} = \left\{ \frac{-i\Delta \omega_j + 1 + i\alpha}{2} G_N (N_j - N_{th}) \right\} E_j + \frac{\kappa_r}{\tau_{in}} E_j (t - \tau) \exp[i\theta_j] + \frac{\kappa_{inj}}{\tau_{in}} E_{inj}(t),
\]

\[
\frac{dN_j}{dt} = J - \frac{1}{\tau_n} N_j - G_N (N_j - N_0) |E_j|^2,
\]

where \( j = 1, 2 \) indicate the response laser 1 and 2, respectively, \( E_j \) represents the complex electric field, \( N_j \) the...
carrier number density, $\kappa_r$ the optical feedback strength, 
$\tau$ the external-cavity delay time, $E_{\text{inj}}$ the complex electric 
field of the injected common random light, and $\kappa_{\text{inj}}$ the 
injection strength. The detuning parameter $\Delta \omega_j$ is defined 
by $\Delta \omega_j = \omega_0 - \omega_j$, where $\omega_0$ is the center optical angular 
frequency of the injected light and $\omega_j$ is that of the $j$th 
response laser. For later use, we define the detuning frequency 
$\Delta f = \Delta \omega_j/2\pi$.

Let $\rho(t)$ and $\phi(t)$ be fluctuations in the amplitude and 
phase of the injected light $E_{\text{inj}}$ defined by $E_{\text{inj}}(t) = E_0[1 + 
\varepsilon \rho(t) \exp[i \phi(t)]]$, respectively, where $E_0$ and $\varepsilon$ are positive 
constants. We assume $\rho(t)$ and $\phi(t)$ are described by the 
stochastic differential equations

$$
\frac{d\rho}{dt} = -\rho/\tau_m + \sqrt{2/\tau_m} \xi(t), \quad (3)
$$

and

$$
\frac{d\phi}{dt} = \sqrt{2/\tau_m} \eta(t), \quad (4)
$$

where $\tau_m$ is a positive constant. In Eqs. (3) and (4), $\xi(t)$ 
and $\eta(t)$ are the normalized white Gaussian noise with 
the properties $\langle \xi(t) \rangle = \langle \eta(t) \rangle = 0$, 
$\langle \xi(t) \xi(s) \rangle = \langle \eta(t) \eta(s) \rangle = \delta(t-s)$, where $\langle \cdot \rangle$ 
denotes the ensemble average and $\delta$ is Dirac’s delta function. 
The amplitude $\rho(t)$ is the Ornstein-Uhlenbeck process, and 
has the properties $\langle \rho(t) \rangle = 0$ and $\langle \rho(t) \rho(s) \rangle = 
\exp[-|t-s|/\tau_m]$. This indicates that the correlation time 
of $\rho(t)$ is given by $\tau_m$. On the other hand, $\phi(t)$ has the 
property $\langle |\phi(t) - \phi(s)|^2 \rangle = 2\tau_m^{-1}|t-s|$. Since $\phi(t)$ has 
the diffusion constant $\tau_m^{-1}$, its characteristic time for 
correlation decay can be defined by $\tau_m$. Therefore, $\tau_m$ 
gives the time scale of fluctuation of $E_{\text{inj}}$. This implies that 
the bandwidth of $E_{\text{inj}}$ is of the order of $\tau_m^{-1}$.

In our numerical simulations, the following parameter 
values were used: $\alpha = 3$, $G_N = 8.4 \times 10^{-13}$ m$^2$s$^{-1}$, $N_0 = 
1.4 \times 10^{24}$ m$^{-3}$, $N_{\text{th}} = 2.018 \times 10^{24}$ m$^{-3}$, $\tau_m = 
8.0\text{ps}$, $\tau = 4.0\text{ns}$, and $J = 1.19\text{J}_\text{th}$, where 
$\Delta \omega_{\text{th}} = N_{\text{th}}/\tau_m$ is the lasing threshold of injection current. 
For this value of $J$, the response lasers have the relaxation 
ocillation frequency 2.0 GHz. We assumed a slight 
detuning between the two response lasers as $\omega_1 - \omega_2 = 0.2$ GHz. As for the injected light, we set $\varepsilon = 0.3$ and 
$E_0 = |0.19J_{\text{th}}/G_N(N_{\text{th}} - N_0)|^{1/2}$. The other parameters 
$\kappa_{\text{inj}}, \kappa_r, \Delta f$, and $\tau_m$ were varied in the simulations.

We are specifically interested in the condition for syn- 
chronization of the response lasers, especially its dependence 
on the parameters which characterize the lasers or 
the injected light. In order to measure the synchronization, 
we use the correlation between the output intensities of the 
two response lasers, $I_j(t) = |E_j(t)|^2$. The correlation 
between $I_1(t)$ and $I_2(t)$ is defined as

$$
C = \frac{\langle (I_1 - \mu_1)(I_2 - \mu_2) \rangle_T}{\sigma_1 \sigma_2},
$$

de (5)

where $\mu_j$ and $\sigma_j$ are the average and the standard deviation 
of $I_j$, respectively, and $\langle \cdot \rangle_T$ denotes the time average. By

Figure 2: Contour plot of correlation $C$ in $(\Delta f, \kappa_{\text{inj}})$ plane 
for response lasers with $\kappa_r = 0.2$, where $\tau_m = 10\text{ps}$.

Figure 3: Temporal waveform and correlation plot of out-
puts of response lasers with $\kappa_r = 0.2$, where $\tau_m = 10\text{ps}$. 
Parameters are $\kappa_{\text{inj}} = 0.5$ and (a), (b) $\Delta f = -50\text{GHz}$ and 
(c), (d) $\Delta f = -10\text{GHz}$.

3. Numerical results

We show an example of the parameter region for syn- 
chronization. It was found that the phase shifts $\theta_1$ and $\theta_2$ 
of feedback light are important parameters, which signifi- 
cantly affect the degree of synchronization. They were set as 
$\theta_1 - \theta_2 = 2\pi(\omega_1 - \omega_2)\tau$ to maximize $C$. We will use 
$\theta_1$ and $\theta_2$ satisfying this relation in what follows. Figure 
2 shows contour plot of $C$ as a function of $(\Delta f, \kappa_{\text{inj}})$ for 
$\kappa_r = 0.2$ and $\tau_m = 10\text{ps}$. The injected light has a broad 
bandwidth of the order of 100 GHz. The condition $C > 0.8$
is satisfied inside the wedge-shaped region bounded by red line. It was observed that $C$ is very close to unity over most part of this region. This numerical result indicates that synchronization by common random light injection is possible even when the injected light has a broad bandwidth. In what follows, we use $C > 0.8$ as a criterion for the synchronization.

In Figs. 3 (a)-(d), we show temporal waveforms and correlation plots of outputs of the response lasers. Figures 3 (a) and (b) correspond to the case of $\Delta f = -50$ GHz and $\kappa_{\text{inj}} = 0.5$, which is outside the synchronization region in Fig. 2 and has a small correlation. These figures clearly show that the response lasers do not synchronize with each other. Figures 3 (c) and (d) correspond to the case of $\Delta f = -10$ GHz and $\kappa_{\text{inj}} = 0.5$, which is a set of values inside the synchronization region. The correlation is $C \approx 1$ and a straight line of $I_1 = I_2$ appears in Fig. 3 (d). This clearly indicates that the synchronization of response lasers occurs.

We examine the effects of the feedback strength $\kappa_r$. Figure 4 shows the synchronization regions in $(\Delta f, \kappa_{\text{inj}})$ plane for different values of $\kappa_r$, where $\tau_m = 10$ ps. The contour lines of $C = 0.8$ are shown for four different values of $\kappa_r$. For each contour line, the synchronization occurs in a region above the line. The synchronization region becomes smaller as the feedback strength $\kappa_r$ increases: it is necessary to supply stronger injection light to achieve the synchronization for larger $\kappa_r$.

Figure 5 shows how the synchronization region depends on the time scale $\tau_m$ of random fluctuations in the injected light. The regions for $C > 0.8$ are shown in $(\Delta f, \kappa_{\text{inj}})$ plane for different values of $\tau_m$. The synchronization occurs above each boundary curve. This result shows that the synchronization is possible over a wide range of $\tau_m$ values, although the minimum value of $\kappa_{\text{inj}}$ necessary for synchronization increases as $\tau_m$ decreases in the regime $\tau_m \leq 100$ ps. The shape of synchronization region changes depending on $\tau_m$. A sharp wedge-shaped region appears when $\tau_m$ is large and the injected light has a relatively narrow bandwidth. In contrast, the region does not have a wedge shape when $\tau_m$ is small and the injected light has a broad bandwidth: the value of $\kappa_{\text{inj}}$ on the boundary curve is almost independent of $\Delta f$ for $\tau_m = 1$ ps.

It is known that the optical frequencies of two synchronized lasers coincide with that of the injected common light due to the injection locking when the injected light has a relatively narrow bandwidth [13, 14, 15]. We calculated the frequency $\Omega_j$ of each laser to examine whether the frequency locking in the synchronized state still occurs for the injection light with a broad bandwidth. We define the frequency $\Omega_j$ as

$$\Omega_j = \lim_{T \to \infty} \frac{1}{2\pi T} \left[ \arg E_j(T) - \arg E_j(0) \right].$$

Figure 6 shows $\Omega_1$ plotted as a function of $\Delta f$ for different values of $\tau_m$, where the injection and feedback strengths are fixed as $\kappa_r = 0.2$ and $\kappa_{\text{inj}} = 1.2$. The results for $\Omega_2$ are similar to those of $\Omega_1$. It is clear that $\Omega_1 \approx 0$ holds in a vicinity of $\Delta f = 0$ for large $\tau_m$, namely, $\tau_m = 1$ ns and 100 ps. This indicates the frequency locking between the optical frequency of a laser and that of the injected light. It turns out from Figs. 5 and 6 that $\Omega_1 \approx 0$ holds roughly over a range in $\Delta f$ where the synchronization occurs, for these two $\tau_m$ values. This observation clearly confirms that the synchronization is accompanied with the frequency locking in the case of large $\tau_m$. In contrast, for small $\tau_m$ cases, i.e., broad bandwidth cases, there is no plateau where $\Omega_1 \approx 0$ holds in Fig. 6. Especially for $\tau_m = 1$ ps, $\Omega_1$ depends on $\Delta f$ almost linearly. This fact
Figure 6: Frequency $\Omega_1$ of electric field $E_1$ vs. $\Delta f$ for $\tau_m = 1$ ns (red line), 100 ps (yellow line), 10 ps (green line), and 1 ps (blue line), where $\kappa_r = 0.2$ and $\kappa_{inj} = 1.2$.

indicates the lack of frequency locking even in the synchronized state in the case of small $\tau_m$. The same phenomenon has been theoretically revealed for two detuned limit-cycle oscillators driven by common white Gaussian noise [10]. Thus, synchronization without frequency locking may be regarded as a characteristic of the case of common random signal driving with broad bandwidth.

4. Conclusions

We numerically studied the synchronization of two semiconductor lasers with optical self-feedback loops, which is induced by common injection of random light with broad bandwidth. We have clarified the parameter conditions for the synchronization in detail. The synchronization is possible over a wide range of bandwidth of the injection light, i.e., for $\tau_m = 1$ ns to 1 ps. It has been found that a common random light with fairly broad bandwidth $\tau_m = 1$ ps can induce the synchronization. The minimum value of $\kappa_{inj}$ for synchronization strongly depends on $\Delta f$ when the bandwidth is relatively narrow, while it is almost independent of $\Delta f$ when the bandwidth is broad enough. It was found that the synchronization is accompanied with frequency locking in the narrow bandwidth regime, while it is without frequency locking in the broad bandwidth regime. In addition, we studied the effects of the feedback strength $\kappa_r$ on synchronization and showed that the stronger injection strength is necessary for the larger $\kappa_r$.
